The University of Melbourne School of Computing and Information Systems COMP10002 Foundations of Algorithms Semester 1, 2023

Assignment 1

Due: 4pm Friday 5 May 2023

Version 1.0

1 Learning Outcomes

In this assignment, you will demonstrate your understanding of arrays, pointers, input processing, and functions. You will also extend your skills in terms of code reading, program design, testing, and debugging.

2 The Story...

Given an array of n sorted numbers, binary search offers a fast $O(\log_2 n)$ -time search to look up for a search key (that is, a number to be located in the array). This means, given an array with one billion numbers, it takes only $\log_2 10^9 \approx 30$ comparisons to locate a search key. While this is very fast, the modern "big data era" calls for even faster solutions. Think about Black Friday shopping events, Amazon needs to support queries to their inventory with billions of products given a product ID, for millions of users (if not more) at the same time. Google Maps is another example, where millions of users may be querying for points of interest given coordinate ranges (e.g., for restaurants within a user's Google Maps app view). Tremendous efforts have been made to scale up these services, including investments on more hardware which later led to the Amazon Web Services.

In this assignment, we will design an algorithmic solution for the problem. Our aim is to further bring down the search time complexity to O(1) (in an ideal case) – too good!

As just mentioned, the goal of number searching is to locate a search key in an array of numbers. This translates to returning the subscript index of a number in the array that equals to the search key (if the search key if found). For example, given an array dataset[] = {5, 12, 18, 44, 52, 58, 64, 93, 98, 98}, and a search key key = 18, a search algorithm should return 2 (the subscript index of 18), as dataset[2] = 18.

A search algorithm thus can be thought of as a mapping function f(key) that takes a search key as the input and outputs the subscript index of key in array dataset. The key to achieve an O(1)-time search algorithm is to find a mapping function that runs in O(1)-time.

Figure 1: A mapping function example

Figure 1 plots a mapping from the numbers in the sample array dataset to their corresponding subscript indices, which form a (blue solid) polyline. This polyline can be approximated by a single linear function $f(\texttt{key}) = \frac{(1-0)key + dataset[1] \times 0 - dataset[0] \times 1}{dataset[1] - dataset[0]} = \frac{key - 5}{7} \text{ (the red dashed line, which is defined using the first two array elements dataset[0] and dataset[1] and their subscript indices 0 and 1). Given a search key key = 18, <math>\lceil f(\texttt{key}) \rceil = 2 (\lceil x \rceil)$ here is the ceiling function that returns the smallest integer greater than or equal to x), which is the subscript index of key = 18 in the array – this is an O(1)-time search!

Of course, we may not always be so lucky. When key = 44, $\lceil f(key) \rceil = 6$, which is not the subscript index of key. In this case, we fall back to a scan (or binary search) on both sides of dataset[6] until key is found or the array boundary has been reached.

We call $|\lceil f(\texttt{key}) \rceil - \texttt{x}|$ where dataset[x] = key the prediction error of the mapping function f for a search key key. Continuing with the example above, when key = 44, the prediction error is |6 - 3| = 3. We can record the maximum prediction error of f for all numbers in dataset. Let this maximum prediction error be err_m . At search time, we only need to search within the range of $[\lceil f(\texttt{key}) \rceil - err_m, \lceil f(\texttt{key}) \rceil + err_m]$. In this case, the search time becomes $O(err_m)$ (or $O(\log err_m)$ with binary search, typically $err_m \ll n$).

The value of err_m thus plays a critical role in the search efficiency, and different strategies have been proposed to limit this value. In this assignment, you will implement one of the strategies and a search algorithm based on the mapping function idea.

What you have read above is the core idea of the so-called *learned indices*, which is a latest development of data indexing techniques based on machine learning.¹ One of your lecturers, Dr. Jianzhong Qi, contributed to this area of research by introducing learned indices into multidimensional data indexing. See https://people.eng.unimelb.edu.au/jianzhongq/papers/ICDE2023_ELSI.pdf for his latest work on how to construct learn indices for multidimensional data efficiently.

3 Your Task

You will be given a skeleton code file named program.c for this assignment on Canvas. The skeleton code file contains a main function that has been partially completed. There are a few other functions which are incomplete. You need to add code to all the functions including the main function for the following tasks.

The given input to the program consists of 12 lines of positive integers as follows:

- The first 10 lines contains 10 unsorted integers separated by whitespace in each line. Together this forms an array of 100 numbers (between 1 and 999, inclusive) to run our search algorithm upon.
- The next line contains a single integer representing a target maximum prediction error err_m that we aim to achieve. This integer will be greater than 1.
- The final line contains one or more integers (separated by whitespace) representing the search keys. There is no predefined upper limit on the number of search keys.

You may assume that the test data always follows the format as described above. No input validity checking is needed. Below is a sample input.

```
164 694 887 133 18 988 851 961 154 223
794 619 973 681 683
                    93 468 433 873 423
389 465 875 346 347 409
                         58 374 286 558
607 704 735 631 768 921 247
                             44 154 464
155 517 551 995 950 132 540 971
660 164 592 882 594 816 799 685 615
 52 691 769 749 297 503 195 785 121
                                    834
    12 985 975 954 784 800 327 222
         98 109 810 934 975 304 282 441
372 970 736
            98 685 179 655 500 210 480
5
18 195 735 975 668 1
```

¹Machine learning in (perhaps overly) simple terms is just to fit the parameter values of mathematical models (e.g., a linear mapping function) to a given set of data samples a.k.a. training data (e.g., an array of numbers).

3.1 Stage 1: Read Input Numbers, Sort Them, and Output the First Ten Numbers (Up to 5 Marks)

Your first task is to understand the skeleton code. Note the use of the data_t type for generalisability in the skeleton code, which is essentially the int type.

Then, you should add code the stage_one function to (1) read the first 10 input lines into the dataset array, (2) call the quick_sort function provided in the skeleton code to sort the dataset array in ascending order (for marking purposes, you are not allowed to use sorting code from other sources, or to create your own sorting function from scratch), and (3) output the first 10 elements in the sorted array.

The output for this stage given the above sample input should be (where "mac:" is the command prompt):

mac: ./program < test0.txt
Stage 1
========</pre>

First 10 numbers: 5 12 18 44 52 58 64 93 98 98

As this example illustrates, the best way to get data into your program is to edit it in a text file (with a ".txt" extension, any text editor can do this), and then execute your program from the command line, feeding the data in via input redirection (using <). In the program, we will still use the standard input functions such as scanf to read the data fed in from the text file. Our auto-testing system will feed input data into your submissions in this way as well. You do not need to (and should not) use any file operation functions such as fopen or fread. To simplify the assessment, your program should not print anything except for the data requested to be output (as shown in the output example).

You should plan carefully, rather than just leaping in and starting to edit the skeleton code. Then, before moving through the rest of the stages, you should test your program thoroughly to ensure its correctness.

You can (and should) create sub-functions to complete the tasks.

3.2 Stage 2: Index with a Single Linear Function (Up to 10 Marks)

Now add code to the stage_two function to:

1. Compute the values of parameters a and b for function $f(\text{key}) = \frac{key + a}{b}$ using the first two elements dataset[0] and dataset[1] of the dataset array. Note that given two points (x_0, y_0) and (x_1, y_1) in Euclidean space, they define a line with the following equation:

$$f(x) = \frac{(y_1 - y_0) \cdot x + y_0 \cdot x_1 - y_1 \cdot x_0}{x_1 - x_0} \tag{1}$$

Note a special case where $\mathtt{dataset[0]} = \mathtt{dataset[1]}$. In this case, $f(\mathtt{key})$ should just return the subscript index of the first of the two elements, which is 0. You can set b=0 and a to be the subscript index of the first of the two elements (that is, 0) to record this special case, such that your function f can be generalised in Stage 3.

- 2. Compute the maximum prediction error of function f over the sorted array dataset (not the target maximum prediction error given in the input data). Hint: You may need the ceil and abs functions from math.h for this computation.
- 3. Output the maximum prediction error, the dataset array element with this error, and the subscript index of the element. If there are multiple elements with this error, output the smallest among them.

The output for this stage given the above sample input should be:

Stage 2

Maximum prediction error: 46

For key: 950 At position: 89

3.3 Stage 3: Index with More Linear Functions to Reduce the Maximum Prediction Error (Up to 17 Marks)

Add code to the stage_three function to read the target maximum prediction error err_m given in the input and implement a strategy that achieves this target by using multiple mapping functions as follows.

- 1. Compute the values of parameters a and b for function $f(\text{key}) = \frac{key + a}{b}$ using the first two elements of the dataset array as done in Stage 2.
- 2. Starting from the third element of the dataset array, compute the prediction error of f for the element. If the prediction error does not exceed err_m , we say that the element is "covered" by function f. Otherwise, we say that the element cannot be covered by f.
- 3. Repeat Step 2 with the rest of the elements until the first element that cannot be covered by f is found. Let this element be dataset[i].
- 4. Store the parameter values of a and b as well as the value of data[i-1]. Hint: A struct typed array will do this nicely. Read Chapter 8 of the textbook if you would like to take this approach, or you can use three arrays for the same purpose. You will need to work out a proper size for the array(s). You can work out this size based on the input data format as described above. You will not need to use dynamic memory allocation for this assignment.
- 5. Repeat Step 1, this time using data[i] and data[i+1] to compute a new mapping function (note: i and i+1 will also be needed in the process; revisit the example equation in Section 2). If there is just one element left, a mapping function with a = n 1 and b = 0 should be created. Here, n is the number of data elements in the dataset array.
- 6. The algorithm should terminate when no more points are to be covered by new mapping functions.

For this stage, the output of your code should be the target maximum prediction error, the list of mapping functions computed, the maximum dataset array element covered by each mapping function. For example, given the sample input above, the output of this stage is:

Stage 3

```
Target maximum prediction error: 5
Function 0: a = -5, b = 7, max element =
Function 1: a = -58, b =
                            5, max element = 133
Function 2: a =
                  14, b =
                            0, max element = 179
Function 3: a = 105, b =
                           15, \max element = 468
Function 4: a = 420, b =
                           20, \max element = 683
                  62, b =
Function 5: a =
                            0, max element = 735
Function 6: a = -667, b =
                            1, max element = 736
Function 7: a = 581, b =
                           19, max element = 810
Function 8: a = 624, b =
                           18, \max element = 973
                  95, b =
Function 9: a =
                            0, max element = 995
```

Hint: For debugging purposes, you may also print out the full sorted dataset array. Make sure to remove the extra printf statements before making your final submission.

3.4 Stage 4: Perform Exact-Match Queries (Up to 20 Marks)

Add code to the stage_four function to search for the search keys given in the input using the mapping functions created in Stage 3.

Given a search key key, the search process with the mapping functions runs as follows:

- 1. If key is smaller than the minimum element or greater than the maximum element in dataset, output "not found!" and terminate the search.
- 2. Otherwise, run a binary search over the array of mapping functions (using the maximum dataset array element covered by each function) to locate the mapping function f covering key.

3. Run a binary search over $[\max\{0, \lceil f(\texttt{key}) \rceil - err_m\}, \min\{\texttt{n}-1, \lceil f(\texttt{key}) \rceil + err_m\}]$ to locate key from the dataset array. Here, max and min are functions to calculate the maximum and minimum value between two numbers, respectively. You need to write code to implement these functions.

Note: You should adapt the binary_search function included in the skeleton code for the two steps above, to output the dataset array elements that have been compared with during the search process. You can create two binary search functions for the two steps separately (without penalties on duplicate code). For marking purposes, you are not allowed to use binary search code from other sources, or to create your own binary search functions from scratch.

The output for this stage given the sample input above is as follows.

```
Stage 4
```

```
Searching for 18:
Step 1: search key in data domain.
Step 2: 735 179 133 64
Step 3: 52 18 @ dataset[2]!
Searching for 195:
Step 1: search key in data domain.
Step 2: 735 179 683 468
Step 3: 195 @ dataset[20]!
Searching for 735:
Step 1: search key in data domain.
Step 2: 735
Step 3: 685 694 735 @ dataset[67]!
Searching for 975:
Step 1: search key in data domain.
Step 2: 735 973 995
Step 3: 975 @ dataset[95]!
Searching for 668:
Step 1: search key in data domain.
Step 2: 735 179 683 468
Step 3: 615 655 681 660 not found!
Searching for 1:
Step 1: not found!
```

Take searching for key = 18 as an example. At Step 2, we start by comparing with the maximum dataset array element covered by mapping function (0 + 10)/2 = 5 (given that there are 10 mapping functions), which is 735 > 18 (see Stage 3 output). We next consider mapping function (0 + 5)/2 = 2, which covers dataset array elements up to 179 > 18. Continuing with this process, mapping function (0 + 2)/2 = 1 covering up to 133 > 18 is the next to considered, followed by mapping function (0 + 1)/2 = 0 covering up to 64 > 18. After this, our search range will become [0, 0], which means that there is just mapping function 0 to be considered. This is the mapping function covering key = 18, and $\lceil f(18) \rceil = 2$ (recall the calculation in Section 2).

At Step 3, a binary search is run over dataset in the range of $[\max\{0, \lceil f(\text{key}) \rceil - err_m\}, \min\{n-1, \lceil f(\text{key}) \rceil + err_m\}] = [0,7]$. The first array element to compare with is dataset [(0 + 8)/2] = 52 > 18. Next, we compare with dataset [(0 + 4)/2] = 18, and the search key is found.

Open challenge (no answer needed in your assignment submission, but you are welcomed to share your thoughts on Ed with private posts): As you may have observed, using our structure may end up with close to $\lceil \log_2 100 \rceil = 7$ comparisons at times which means it is not always better than a naive binary search. This is because we have simplified the learned index structure for the assignment purpose. In practice, we can choose the array elements to compute a mapping function with smarter strategies, such that each mapping function can cover more array elements, and hence there are fewer mapping functions to examine for Step 2 above. Also, the maximum elements of the mapping functions form another array, which can be indexed by another layer of mapping functions, and we can do this recursively to form a hierarchical structure. Can you think of other strategies to make learned indices even better?

4 Submission and Assessment

This assignment is worth 20% of the final mark. A detailed marking scheme will be provided on Canvas.

Submitting your code. To submit your code, you will need to: (1) Log in to Canvas LMS subject site, (2) Navigate to "Assignment 1" in the "Assignments" page, (3) Click on "Load Assignment 1 in a new window", and (4) follow the instructions on the Gradescope "Assignment 1" page and click on the "Submit" link to make a submission. You can submit as many times as you want to. Only the last submission made before the deadline will be marked. Submissions made after the deadline will be marked with late penalties as detailed at the end of this document. Do not submit after the deadline unless a late submission is intended. Two hidden tests will be run for marking purposes. Results of these tests will be released after the marking is done.

You can (and should) submit both **early and often** – to check that your program compiles correctly on our test system, which may have some different characteristics to your own machines.

Testing on your own computer. You will be given a sample test file test0.txt and the sample output test0-output.txt. You can test your code on your own machine with the following command and compare the output with test0-output.txt:

```
mac: ./program < test0.txt /* Here '<' feeds the data from test0.txt into program */
```

Note that we are using the following command to compile your code on the submission testing system (we name the source code file program.c).

```
gcc -Wall -std=c17 -o program program.c -lm
```

The flag "-std=c17" enables the compiler to use a modern standard of the C language — C17. To ensure that your submission works properly on the submission system, you should use this command to compile your code on your local machine as well.

You may discuss your work with others, but what gets typed into your program must be individual work, **not** from anyone else. Do **not** give (hard or soft) copies of your work to anyone else; do **not** "lend" your memory stick to others; and do **not** ask others to give you their programs "just so that I can take a look and get some ideas, I won't copy, honest". The best way to help your friends in this regard is to say a very firm "no" when they ask for a copy of, or to see, your program, pointing out that your "no", and their acceptance of that decision, is the only thing that will preserve your friendship. A sophisticated program that undertakes deep structural analysis of C code identifying regions of similarity will be run over all submissions in "compare every pair" mode. See https://academichonesty.unimelb.edu.au for more information.

Deadline: Programs not submitted by 4pm Friday 5 May 2023 will lose penalty marks at the rate of 3 marks per day or part day late. Late submissions after 4pm Monday 8 May 2023 will not be accepted. Students seeking extensions for medical or other "outside my control" reasons should email the lecturer at jianzhong.qi@unimelb.edu.au. If you attend a GP or other health care professional as a result of illness, be sure to take a Health Professional Report (HRP) form with you (get it from the Special Consideration section of the Student Portal), you will need this form to be filled out if your illness develops into something that later requires a Special Consideration application to be lodged. You should scan the HPR form and send it in connection with any non-Special Consideration assignment extension requests.

And remember, Algorithms are fun!
